Abstract— Diabetes is an expeditiously increasing worldwide complication which is characterized by defective metabolism of glucose that causes longstanding disorders and collapse of various organs of human body. Diabetic Retinopathy (DR) is the most common diabetic eye disease. Nowadays it is the primitive causes of blindness and visual impairment in adults. This can be prevented if diagnosed and treated in its early stages by detecting the microaneurysms(MAs) and Exudates in the retina of the diabetic patient. The proposed work develops an adequate system for ophthalmologist to analyze the MAs and exudates. The abnormalities in the captured colour fundus image are detected using digital image processing (DIP) techniques by applying pre-processing, morphological and other signal processing operations. The extracted features are used to classify the severity of DR with average accuracy of 97% and displays on GUI.

Key Terms— Diabetic retinopathy (DR), morphological processing, digital image processing(DIP), microaneurysms (MAs), exudates, disease severity.

INTRODUCTION

Diabetes is a protracted disease caused by insufficient insulin being produced by the pancreas or by the ineffectiveness of the insulin produce. In recent years, diabetes has reached worldwide epidemic proportions. The World Health Organization attributes the increased occurrence of the disease to lifestyle and economic change. Diabetic Retinopathy (DR) is a general term for all disorders of the retina caused by diabetes. It typically begins as small changes in the retinal capillaries. The smallest detectable abnormalities, microaneurysms (MA), appear as small red dots in the retina and are local distensions of the weakened retinal capillary. Due to these damaged capillary walls, the small blood vessels may rupture and cause intraretinal haemorrhages (HA). In the retina, the haemorrhages appear either as small red dots indistinguishable from microaneurysms or larger round-shaped blots with irregular outline.

DR also increases the permeability of the capillary walls which results in retinal oedema and hard exudates (HE). The hard exudates are lipid formations leaking from the weakened blood vessels and appear yellowish with well defined borders. If the local capillary circulation and oxygen support fail due to obstructed blood vessels, pale areas with indistinct margins appear in the retina. These areas are small microinfarcts known as soft exudates(SE).

LITERATURE SURVEY

V.Vijayakumari and N.Suriyanarayanan et al. [1] uses mathematical morphology for extracting exudates, optic disk and blood vessels. Here morphological opening and closing operations of different sizes are used to detect hard exudates, but one of the main drawbacks of morphological operation is the size of structuring element suitable for one image is not be suitable for another image. Saiprasad Ravishankar et al [2] also uses mathematical morphology to detect hard exudates but it uses a linear classifier for classifying the patches based on their edge strength. Hussain F.Jaafar et al [3] introduced a pure splitting technique for detection of exudates in retinal images. This technique uses an adaptive thresholding based on a novel algorithm for pure splitting of the image. S.Kavitha et al [4] uses mathematical morphology and pure splitting technique to detect faint exudates. Sopharak et al [5] used a Naïve Bayes classifier to detect exudates. The main drawback of Navie Bayes classifier is it misses the faint exudates. R.Vijayamadheswaran et al [6] proposed detection of exudates using a combination of contextual clustering
and Radial basis function. In this technique all the fundus images are transformed to a standard template image condition. Detection of exudates is accurate when the fundus images are captured with good quality. Garcia et al [7] detects Hard exudates using neural network (NN) approach. Here three NN classifiers were investigated which includes multilayer perceptron (MLP), radial basis function (RBF) and support vector machine(SVM). Vallabha et al in their work titled “Automated detection and classification of vascular abnormalities in diabetic retinopathy”[20] applied the use of scale and orientation of selective Gabor filter to detect and classify the retina images into mild or severe case.

**SYSTEM METHODOLOGY**

The proposed system automatically detect the blood vessels, microaneursym, and exudates of the captured input fudus image and classify the result into either normal or DR case. Fig. 1 shows the block diagram of the proposed system.

![Proposed system diagram](image)

Eye fundus photography is the preferred diagnostic modality because it is reliable, non-invasive and easy to use. In contrast to traditional ophthalmoscopy, it allows to record diagnostic data and enable the expert consultation afterwards, and more importantly the eye fundus photography results in a better sensitivity rate, that is, a better detection rate of abnormal eye funduses. In case of DR diagnosis the strong recommendation is to take both colour image and red-free eye images, where two images are captured by focusing the 45deg field-of-view fundus camera to macula and optic disc. For long-term diabetic patients, two-field 60deg photography is recommended since the neovascular changes that need treatment are typically found in the periphery, even if the changes in the central areas of the retina are slight.

**Pre-processing stage** is considered as the backbone of this research work. In detecting the abnormalities associated with fundus image, the images have to be pre-processed in order to correct the problems of uneven illumination problem, nonsufficient contrast between exudates and image background pixels and presence of noise in the input fundus image. This stage is also responsible for colour space conversion and image size standardization for the system. Pre-processing is also very much necessary for the reliable extraction of features and abnormalities as feature extraction and detection grading algorithms give poor results in the presence of noisy background.

In the RGB images, the green channel exhibits the best contrast between the vessels and background while the red and blue ones tend to be more noise. Hence green channel is used for further processing. In next step the green channel image is converted into a gray scale image, as the retinal blood vessels appear darker in the gray image. All the features like blood vessels, MAs etc. are hidden in the background and are not clearly visible. Contrast enhancement is performed to improve the image quality. One of the problems associated with fundus images is uneven illumination. Some areas of the fundus images appear to be brighter than the other. Areas at the centre of the image are always well illuminated, hence appears very bright while the sides at the edges or far
away are poorly illuminated and appears to be very dark. In our research work Adaptive histogram equalisation method (AHEM) is used. AHEM gives better performance, higher processing speed and work well for all images of different sizes. DWT is applied for this image.

Detection of Blood vessels: Accurate segmentation of the retinal blood vessels is very essential prerequisite step in the identification of the retinal anatomy and pathology. A green channel image is processed with image segmentation and combined with the mask layer. These two images are compared and the differences are removed. The obtained image would represent the blood vessels of the original image.

Detection of Exudates: Exudates appeared as bright yellow-white deposits on the retina due to the leakage of blood from abnormal vessels. Their shape and size will vary with the different DR stages. The grayscale image is first preprocessed and a K-nearest neighbors algorithm, together with a static classifier combination scheme, has been used to determine whether a retinal image contains exudates. The exudates are detected after removing the border, optical disk and non-exudates area.

Detection of Microaneurysms: MAs appeared as small dark round dots (~15 to 60microns in diameter) on the fundus images. They are small bulges developed from the weak blood vessels and are the earliest clinical sign of diabetic retinopathy. Hence, it is essential to detect them during the mild stage. The number of MAs would increase with the stage of the retinopathy. Morphological processing algorithms are the most
commonly used algorithms. A spot lesion detection algorithm using multiscale morphological processing is used to detect sensitive MAs.

The feature vector used for classification stage consists of following important features obtained from feature extraction and image segmentation stage. The extracted features are as follows:

i) **Area of blood vessels**: The total number of white (vessel) pixels in the blood vessel segmented image.

ii) **Area of exudates**: The total number of white pixels in the exudates segmented image.

iii) **Area of MA**: The total number of white pixels in the MA segmented image.

iv) **Contrast**: Measure of the intensity contrast between a pixel and its neighbor over the whole image.

v) **Homogeneity**: Measures the closeness of the distribution of elements to the diagonal.

vi) **Correlation**: Linear dependency of the gray level values in the co-occurrence matrix.

vii) **Energy**: Sum of squared elements in the co-occurrence matrix.

The extracted feature values will have different ranges of values, therefore it is necessary to normalize the values to an acceptable range.

**EXPERIMENTAL RESULTS AND DISCUSSION**

In our research work, for training, 70 images (35 normal and 35 DR images) and for testing, 170 images (85 normal images and 85 DR images) are used and their features are extracted. Then these features are used by the SVM classifier to classify the input images into Normal and DR (MA/Exudates) images. The implementation and testing of this work is carried out using Pentium IV – 2.7MHz, 1Gb DDR RAM and 250Gb Hard disk with windows XP operating system. MATLAB version used is 7.9.

**CONCLUSION**

In our research work the digital image processing techniques like pre-processing, image segmentation and feature extraction are applied to publicly available retinal fundus image databases like STARE (Structured Analysis of Retina), DRIVE (Digital Retinal Images for Vessel Extraction) and also images provide by NETHRA Hospital, Bangalore. The extracted features are used to train the SVM classifier which provides average classification accuracy of 97%.
